Abstract

Background: This research investigates patient-centered mobile health (mHealth) technology in terms of the secondary user experience (UX). Specifically, it examines how personal mobile technology, under patient control, can be used to improve patient-provider communication about the patient’s healthcare during a patient’s first visit to a provider. Common ground, a theory about langue use, is used as the theoretical basis to examine interactions. A novel concept of this research is that it is one of the first empirical studies to explore the relative meaningfulness of a secondary UX for specific healthcare tasks.

Objective: The objective of this study was to investigate the extent that patient-operated mHealth technology can be designed to improve the communication between the patient and provider during an initial face-to-face encounter.

Methods: The experimental study was conducted in two large Midwestern cities from February 2016 to May 2016. A custom designed smartphone application prototype was used as the study treatment. The experimental design was post-test-only control group and included video recorded simulated face-to-face clinical encounters in which an actor role-played a patient. Experienced clinicians consisting of doctors ($n = 4$) and nurses ($n = 8$) were the study participants. A thematic analysis of qualitative data was performed. Quantitative data collected from time on task measurements was analyzed using descriptive statistics.

Results: Three themes that represent how grounding manifested during the encounter, what it meant for communication during the encounter, and how it influenced the provider’s perception of the patient emerged from the qualitative analysis. The descriptive statistics were important for inferring evidence of communication efficiency and effectiveness for providers. Overall encounter and task times averaged slightly faster in almost every instance for the treatment group.
than the control group. Common ground clearly was better in the treatment group, indicating that
the idea of designing for the secondary UX to improve provider outcomes has merit.

Conclusions: Combining the notions of common ground, human-computer interaction design,
and smartphone technology, resulted in a prototype that improved the efficiency and
effectiveness of face-to-face collaboration for secondary users. The experimental study is one of
the first studies to demonstrate that an investment in the secondary UX for high payoff tasks has
value but that not all secondary UXs are meaningful for design. This observation is useful for
prioritizing how resources should be applied when considering the secondary UX.

Introduction

Statement of the Problem

The ubiquity of smartphones gives patients access to many applications (apps) that can potentially support healthcare needs. These types of technologies allow patients to track and trend various health behaviors that they may subsequently want to share with healthcare providers. In this context, healthcare providers become what is known as secondary users a term from the human-computer interaction (HCI) discipline that reflects a type of user who is affected by the main or primary users operation (i.e. the patient) of a technology. [1-3]. Primary users, on the other hand, are the dominate operators that control the system and the dissemination of its information, and are patients in this context [1]. Some researchers believe that secondary user experiences (UXs) have the potential to improve collaboration and satisfaction in a variety of settings and, as such, advocate for its inclusion in interactive systems design [4-6]. However, little is known about the secondary user’s experience, especially in the context of healthcare provider encounters.

Recently, it has become common for more people to access the Internet through mobile devices than personal computers (PCs) [7]. The advent of always-internet-connected mobile technologies portends a wider set of UXs than previously envisioned. The lack of any practical geographic or temporal restrictions on the use of some types of patient-centered health information technology (HIT), such as a smartphone personal health record (PHR) app, is a recent phenomenon that impacts users and their experiences. Anytime someone acts with an interactive system through an interface in public, he potentially creates a UX for others; this is the secondary UX. With more than 165 million smartphone users in the U.S. as of 2014, secondary UXs have the potential to become routine [8].
The ubiquity of smartphones gives patients access to technologies that can support their healthcare needs in ways previously unavailable to lay people. Pew Research reported that, within a 1-year period, 62% of U.S. smartphone owners used their devices to look up health information [9]. The ability of smartphones to store and manage information allows patients to track and trend health data and share this data with healthcare providers in a manner that informs clinical decision-making. It is in this context that we believe healthcare providers are interesting as secondary users of patient-controlled devices. In light of this assessment, we decided to investigate patient-centered mobile health (mHealth) technology in terms of the secondary UX. Specifically, this research examines how personal mobile technology, under patient control, can be used to improve patient-provider communication about the patient’s healthcare during a patient’s first visit to a provider.

A novel concept of this research is that it is one of the first empirical studies to explore the relative meaningfulness of a secondary UX for a specific task. Not all UXs are likely to have value during task-oriented communication. In healthcare, patient health often relies upon successful collaborations between patients and providers [10]. Because there are often common tasks for specific types of encounter—for example a first face-to-face encounter between a provider and new patient—such tasks can be anticipated and designed for during a user centered technology design process. However, before designing technology interventions for such tasks, it is important to understand which tasks benefit most from a technology solution. This research, through its emphasis on meaningfulness, provides a model for evaluating secondary UX value for a communication.

Secondary users have been identified in the medical informatics literature but operationalized in terms of patients. This research introduces the opposite phenomenon and looks
at secondary users as providers. It is in this context that we explore how a patient as a primary user can manage technology in a way that improves outcomes for providers who are secondary users.

To meaningfully improve HCI design for the secondary user, we must take into consideration the dynamic interplay between both types of users. This research does this by investigating secondary UXs according to common ground, a communication theory about language use. Two assumptions underpinning this research are that (1) the creation of common ground is a key element of the secondary UX that contributes to improved communication and (2) that interfaces for interactive systems can be designed to facilitate the creation of this key element.

The user type most often researched is the primary user and investigations about secondary users are limited [11]. However, the HCI literature about secondary users remains sparse—which means that the technology is only understood from the perspective of one user type. Inbar and Tractinsky [12] reported that secondary users are missing from both the theoretical and practical perspectives in HCI. Consequently, there is little research that exists to empirically demonstrate why secondary users should be included as a consideration in the design of technology. The currently available research merely indicates that secondary UXs exist and that secondary users are a relevant stakeholder group [3, 11, 13]. Healthcare offers and the increasing emphasis on patient-centered technology, is an especially vital context in which to study the secondary UX because PHR apps are an example of HIT where one person’s use creates UXs for others.

Another shortcoming in the HCI literature about secondary users is the lack of a theoretical basis to explain why secondary users are relevant and should be considered in
technology design. We believe that common ground can fill this void. Common ground, a component of effective collaboration, is established when people have certain knowledge in common and know that they have this knowledge in common [14]. Our research revealed a gap in healthcare knowledge between patients and providers that can potentially be bridged with the aid of technology [15-17]. Such a knowledge disparity is not surprising since patients are laypeople and providers are experts regarding healthcare, which can make the attainment of common ground between them elusive during an encounter. The short duration of encounters can further constrain communication and information sharing, also making common ground difficult to obtain. While improving patient access to health information leads to increased patient participation in health-related decision-making, it is not merely the access to data that creates this impact [18]. The authors believe that it is an improvement in common ground between the patients and their providers that makes superior patient engagement possible. Technology designs that reduce ambiguity in communication between patients and providers have the potential to improve common ground.

**Theoretical Model**

Common ground theory provides the theoretical model for this research. Common ground is defined as “a proposition $p$ is common ground if: all the people conversing know $p$ and they all know they know $p$” [19]. The theory was developed by Clark [20] and explains how people achieve sufficient shared knowledge to successfully complete a communication. *Grounding* is the process to make communication effective and common ground is created as a result of the grounding process [21].

During face-to-face meetings, the ability to share content with someone can be limited by the lack of interactivity of the physical tools (e.g., pen and paper) used by the team members
One of the attractions of common ground for secondary UX research is the idea of external representation. External representation is a way to represent components of the communication in physical form. Clark [20] provided an example of a chess game with the board and pieces serving as external representations of the players. In HCI, a smartphone interface that displays objects of interest to primary and secondary users is an external representation. Direct manipulation interfaces (e.g., graphical user interfaces) have provided excellent support for grounding for many years [23]. Thus, the relation between computer interfaces and grounding is already established and does not require additional explication for this study.

Constraints on Grounding

Actions are important components of common ground. A joint action occurs when people intend to do their parts in the communication and believe that the joint action includes their parts and the other participants’ parts [19]. Common ground is incrementally built based upon the history of joint actions [24]. When joint actions are mediated by interactive systems, the technology places constraints on the establishment of common ground. Constraints are positive in grounding because they reduce ambiguity [19]. The more constraints supported by a technology because of different combinations of devices and interfaces, the better [24]. There are eight constraints for grounding (see Table 2).

Table 1: Constraints on Grounding

</tbody>
</table>
Constraints can be used to predict the problems that people will have with an information system by evaluating which ones are present or absent when using the system [19]. The concept of constraints means that it is possible to anticipate what the UX will be with a product for a particular user type. Since the secondary UX can be anticipated through the evaluation of the constraints, it can be designed for during product development. The ability to predict the experience means that common ground theory can be used to explain problems that people have with an information system in certain contexts [25].

Constraints and Smartphones

Unlike most communication technologies, smartphones can support all constraints in a face-to-face setting. Table 3 shows comparisons of communication mediums and constraints (“X” is a supported constraint). The fact that smartphones allow users to switch back and forth between functionalities (e.g., email or text messaging) seamlessly is an exciting prospect and important for grounding. For example, smartphone users do not have to access a fixed system or workstation to send and receive non-telephonic messages because they have apps that perform several functions.

The potential to improve how language is used during the patient-provider encounter and thus, increase the efficiency of communication between members of the dyad, makes the notion of common ground salient when examining primary and secondary user collaborations. Research suggests that well-designed collaborative technologies speed up the development of common ground by allowing teams to share knowledge, manage actions, and make decisions efficiently [26]. Fortunately, a model to define working with technology in the context of common ground exists. Collaboration mechanics (Table 1), the development of which was influenced by Clark [20] and his work on common ground theory [27], can be utilized to model collaboration with technology. Therefore, the relations among collaboration mechanics, common ground, and secondary user satisfaction are examined in the experimental study.

Research Questions

Even though the HCI literature acknowledges that secondary UXs can occur, it does a poor job of revealing how to evaluate the importance of them for an interaction. It is the authors’ contention that the value of secondary UXs in a unique context should be identified to assess its merit for design. Once this is understood, it becomes possible to make an informed decision about how a secondary UX may or may not improve communication. Common ground provides the vehicle in this research to evaluate the quality and importance of a secondary UX during a clinical encounter. The research questions emphasize how common ground is used to demonstrate the relation of language to digital systems, in a manner that results in better communication in an envisioned healthcare setting.

The research questions for this study are:

RQ1: To what extent do smartphone apps designed using collaboration mechanics support grounding (the process of creating common ground) between primary and secondary users during face-to-face collaborations?

RQ2: To what extent do smartphone apps designed to support grounding impact secondary users’ satisfaction during face-to-face collaborations?

![Figure 1](image-url)  
**Figure 1:** The conceptual model for the research questions.
Method

Design
This two-group randomized experimental study with post-test measures explored the effect of a prototype HIT compared with a control group (no HIT) on common ground and secondary user satisfaction in a simulated clinical encounter using both quantitative and qualitative methods. A custom designed HIT was prototyped for use as the experimental treatment. Patient-provider communication was investigated during the performance of three tasks: problem identification, discussing a patient’s medical history, and medication reconciliation.

Setting and Sample
The study was conducted between February and May 2016 in two large Midwestern cities. This study used simulated face-to-face clinical encounters using a trained patient actor. Experienced clinicians consisting of doctors and nurses were the study participants. Participants were recruited using snowball sampling and email solicitations. All participants received monetary compensation. An adult male with physical characteristics closely matching the scenario and more than a decade of professional and community theater acting experience, was hired (with monetary compensation) to role-play the patient. The same actor was used for all simulations.
Participants

Materials and procedure. The custom designed HIT prototype used as the treatment for the study was a smartphone PHR app. A PHR is a private, secure, electronic, web-based tool that people can use to communicate with their providers and access, manage, and share their personal health information [28-30]. PHRs are an example of HIT with primary (i.e., the patient) and secondary (i.e., the provider) users, two stakeholders with different knowledge and priorities who need to collaborate to make treatment decisions. Extensive preliminary work before the study was done to create the prototype as an mHealth platform to support both types of user [15, 17].

Development of the prototype. The prototype was developed as a WordPress website so that it could be accessed regardless of smartphone manufacturer and operating system. The trained patient actor’s personal smartphone, a Samsung Galaxy Prevail LTE (Figure 3) Android Version 4.4.4, was used to access the prototype during all simulations. The trained patient actor used his own personal smartphone with the prototype installed to minimize training requirements for using the custom designed HIT prototype during the simulation.
The prototype incorporated buttons labeled as “Patient” and “Provider” at the bottom of each page as a switching mechanism so that tailored views of information contained within the prototype were available for primary and secondary users. Before sharing information with providers, the trained patient actor selected the provider button, which changed the view from his patient view to a context tailored for providers. These different views of information were necessary to improve communication and enable the grounding [15].

![Figure 3: Example Samsung Galaxy Prevail LTE showing the medications screen.](image)

*Simulation scenarios.* Both the experimental and control groups participated in a simulated clinical encounter. The scenario required that a provider see a patient for the first time. The reason for the patient’s visit was that he had suffered a rash, which had healed and was no longer visible. As part of the scenario the provider was required to perform three tasks with the trained patient actor: problem identification, take a medical history, and medication reconciliation.
**Development of simulation scenarios.** The orientation and training of the trained patient actor was extensive. The trained patient actor reviewed online videos of simulated clinical encounters that included the tasks required for role-play. After reviewing the videos, a rehearsal training session with an experienced (13 years) registered nurse (RN) who has a Ph.D. (Nursing Science) and is an assistant professor of nursing at a large Midwestern university, was conducted. After the session, the simulation documentation was revised and a checklist to assess treatment fidelity was created. The checklist enhanced the internal and external validity by ensuring that the trained patient actor addressed standardized areas with providers and ensured that the study could be replicated [31]. A second rehearsal using the treatment fidelity checklist as a guide was telephonically conducted. The simulation scenario was then pilot tested for feasibility of study procedures. For this feasibility demonstration we recruited one doctor in the control group and one advanced practice registered nurse (APRN), in the treatment group. Finally, a review of the pilot test simulation videos with the trained patient actor was completed before beginning the study.

**Control group simulation.** For the control group, the trained patient actor simulated real patient behavior during a typical encounter by relying on memory to share information with the study participant about the problem that sparked the visit (rash), medical history, and current medications. The medical history for the scenario included multiple ailments: type 2 diabetes mellitus, obesity, hypertension, and high cholesterol. Four medications (Table 4) were part of the patient profile and were expected to be reviewed during medication reconciliation.
Treatment group simulation. The treatment group was shown an image of the rash by the trained patient actor in addition to receiving a verbal description of the ailment. The image used for the rash was of a patient with bullosis diabeticorum, a blistering condition that heals in a few weeks. For medication reconciliation, details about the medications were shared with the treatment group from the prototype by the trained patient actor. For the medical history tasks, the prototype was not offered to members of the treatment group unless they specifically made a request to look at the information on the device (there were no provider requests to review medical history on the prototype). Before sharing information from the prototype with participants, the trained patient actor switched the view of information from the primary user’s view to the secondary user’s view.

Variables. The independent variable was the presence or absence of the prototype. The dependent variables were common ground and secondary user satisfaction. The participant’s perception of performance was also measured because of its likely impact upon satisfaction. Common ground and the remaining variables were measured by analyzing the simulation videos, Likert scale responses, and interview transcripts. The details of the three measures to evaluate the presence or absence of the treatment are:

1. Recordings: The simulation was video recorded for later analysis with NVivo 11 (a qualitative data analysis software package).
2. Questionnaire: Upon the conclusion of the scenario, the participants completed a 7-point Likert scale questionnaire, which was composed of demographic questions and a set of 15 psychometric scales measuring satisfaction, common ground, and performance.

3. Interviews: Semi-structured interviews were audio recorded and conducted with each participant after the simulation. The results were transcribed using the TranscribeMe! service provided through NVivo 11. The transcriptions were clean verbatim in which filler words (e.g., umm, ah, and you know) were removed. Irrelevant concluding remarks were deleted (e.g., closing courtesies). The transcriptions were of good quality. When errors were discovered, they were reviewed, crosschecked, and corrected based upon the audio recordings.

During the study, an emphasis was placed on collecting rich qualitative data, which is gained when saturation is reached. The study sample size was considered adequate because saturation had been reached during earlier phases of this project with similar sized groups. And saturation was, in fact, achieved during the experimental study. A statistical power analysis indicated that the sample size was too small for hypothesis testing [32]. In lieu of this type of testing, descriptive statistics were used to compare interactions with and without the presence of the prototype. These factors, when taken together, ensured adequate investigation of the dependent variables.

Procedure

The study was performed at a location selected by the study participants. Hospital treatment rooms and administrative or public spaces in medical facilities and academic buildings were typical. At the beginning of each iteration, the participant was asked to
review the study information sheet. The scenario was reviewed with the participant, who was then provided with a pen, clipboard, and paper for taking notes during the simulation. Next, the simulation began, with the use of video recording.

Due to the different specialties and practices encountered during the study, it was impossible to anticipate the flow of the conversation during each simulation. The actor was authorized to incorporate real-life experiences as necessary to maintain realism during the simulation. For example, discussions about diet and exercise mimicked the trained patient actor’s real-life experiences.

After each simulation, the trained patient actor’s performance was reviewed, and behaviors corrected as necessary. The potential effect of actor learning was controlled through training, the use of checklists for treatment fidelity, and counterbalancing between the control and treatment groups [31, 33]. Consistency was maintained as much as possible. Minor errors completed by the actor did not disrupt the study as long as the actor was consistent throughout the duration of the simulation.

Qualitative Analysis

A thematic analysis of the videos and semi-structured interview transcripts was performed using NVivo 11. This form of analysis was preferred because it is the most common approach to evaluating qualitative data in healthcare research [34]. The videos were coded by importing them into NVivo 11, reviewing each video within the software, selecting parts along the range of the media using the software tools, and assigning the range to an appropriate coding container. Summary transcriptions of the videos were also created within NVivo 11, showing general topics of conversation at selected points in the video (e.g., medication reconciliation or problem identification). The audio recorded,
semi-structured interviews were transcribed, as described earlier, and coded within NVivo 11.

There were three rounds of coding with the first round being done manually within the software. During this round of coding, concepts were merged, revised, and discarded as patterns became more obvious. The second round relied upon the analytical software tools of NVivo 11 to analyze results from the first round of coding and create a basic concept map. The map was used to sort the concepts that resulted from the first round of coding and aid in reorganizing them into a hierarchical system for analysis. The third round of coding scrutinized the data based upon membership in the control or treatment group and evaluated how the content diverged thematically between the groups. A matrix query by assignment to experimental group was run to display the frequency of the coding in each major category of joint action. This round of coding was used to break out details of the data to satisfy the research questions. As a result, themes for the control and treatment groups were identified. The analysis revealed that both groups accomplished a substantial level of grounding for the medical history task. Consequently, it was not coded in detail because the analysis of the task, in and of itself, would not contribute to answering the research questions.

Quantitative Analysis

Descriptive statistics were employed because of their importance for inferring evidence of communication efficiency for the providers. Descriptive statistics of means, standard deviations, maximums, and minimums were calculated using SPSS 23. The post-test questionnaires were also evaluated using SPSS 23.
Each video was studied to assess the amount of time spent on the three scenario tasks (i.e., problem identification, medical history, and medication reconciliation) and the percentage of time the tasks consumed of the entire encounter. The efficiency of the encounter was assessed based upon the descriptive statistics for time spent on the three required tasks and the overall duration of encounters. The main effectiveness measure of encounters between the control and treatment groups also relied on descriptive statistics. In this case, they were used to evaluate the amount of time spent on patient education, which providers throughout the research identified as an important task to perform with patients. Finally, descriptive statistics were used to analyze the post-test questionnaires and compare responses between the control and treatment groups.

Results

Thirteen nurses and doctors participated in the experimental study, with 12 included in the final analysis. One participant became frustrated during the simulation and requested that the video recording cease. The subsequent interview revealed that she normally used
an electronic medical record (EMR), which is an electronic version of a patient chart, and followed a standardized routine when interviewing patients (an EMR was not provided as part of the scenario). The lack of an electronic tool made her feel as if she was not providing quality service to the trained patient actor, which caused her to become frustrated and culminated in her request to cease the video recording. Consequently, these results were excluded from the final analysis.

The backgrounds of the final 12 participants, by assignment to control group and treatment group, are shown in Table 5. Two of the participants were educators and no longer interacted with patients. One had transitioned to teaching within the six months prior to the study and the other had 19 years of prior nursing experience. A third participant had shifted to case management within six months prior to the study and had more than 25 years of experience in nursing. The three participants had the necessary skills to perform the scenario tasks and were qualified for the study.

The professional experience of the participants varied from less than one year to more than 25 years (Table 6). All participants were familiar with the basic technologies used in the study. Each participant owned a smartphone and had 11 or more years of experience using computers. Nine of the participants reported owning tablet computers.
Three themes emerged from the thematic analysis. The themes ultimately represent how grounding manifested during the encounter and what it meant for communication during the encounter and how it influenced the provider’s perception of the patient. The themes are discussed below.

- **The patient is engaged in his own healthcare.** If a patient is willing to take the time to manage his health information electronically, then it is an indication that he is engaged in his own healthcare.

- **The information is trustworthy.** The use of sophisticated technology by patients implies a higher trustworthiness of information—or, at least, the same level of trustworthiness as other traditionally accepted (but low use) methods (e.g., bringing medication bottles to an appointment).

- **There is enough information at an acceptable level of quality for some level of decision-making to be obtained.** This amount of information, and its quality, does not mean that there is a diagnosis. It means that better planning is performed with the patient, even if that plan does nothing, because everything appears to be on track.

In addition to the basic scenario tasks, patient education emerged as a desired discussion topic with patients in the post-test interviews for most participants. Since patient education emerged as a topic of broad concern to participants, patient education discussions about the rash, medical history, and medications were coded for the time analysis (see quantitative analysis section for these results). Time spent on general nutrition, health and fitness, and similar counseling was not evaluated.

In general, the trained patient actor’s use of the smartphone seemed to improve provider patient care efficiency during the encounter. The overall encounter and task times (Table 7) averaged slightly faster in almost every instance for the treatment group than the control group. Task times were faster in the control group for the medical history task, which can be explained by the fact that not all providers completed the task. As such, the overall mean was artificially reduced for the control group. Finally, standard deviations generally clustered more closely around the mean for tasks in the treatment group than the control group.
Figure 6: The patient provides accurate medication information by using the prototype to augment his memory, making the attainment of common ground possible.

A benefit of patient care efficiency might be related to the fact that the providers had more time to conduct patient education discussions. The mean for every educational task was higher for the treatment group than the control group. This difference likely contributed to the higher percentage of the encounter time overall (i.e., time spent on the three tasks by the treatment group).

The emphasis on task completion is also relevant for an analysis of patient education. Although efficient and effective patient care is not always correlated, we argue that time is another indicator of a more effective use of provider time in the study. The importance of patient education to providers underpins this analysis. If the efficient use of time leads to the discussion of additional important information (i.e., patient education), then the encounter can be considered more effective.

Note. Rash = Time discussing the problem, Med Rec = Time discussing medication reconciliation, History = Time discussing medical history. The mean times for any patient education (Ed) related to a specific task are to the right of the specific task. % Tasks = The percentage of the total encounter time spent on the three tasks. The * indicates a task for which partial common ground was achieved and the † indicates a task for which common ground was achieved.
The quantitative analysis of the post-test questionnaire examined secondary user perceptions of satisfaction, common ground, and performance. For the post-test questionnaire, a Cronbach’s α reliability analysis (Table 8) was performed on all the subscales using SPSS 23. To improve the reliability of the satisfaction subscale, two items were removed. This removal increased the reliability to ≥ .80, which is good reliability [35]. Reliability for the common ground and performance subscales were ≥ .80 and .90, respectively, which are good and excellent reliabilities, respectively [35].

The descriptive statistics for each subscale (Table 9) show higher means for the control group than the treatment group, indicating that members of the control group perceived that they had a higher level of satisfaction, common ground, and performance than members of the treatment group. Standard deviations show better clustering around the mean for the treatment group on each subscale, which could indicate a better consensus among the treatment group members, reflecting a more accurate evaluation of satisfaction, common ground, and performance than in the control group.

</table>
In summary, the experimental study provided substantial insight about grounding in the context of a face-to-face clinical interaction. The research questions were comprehensively addressed during the study. Grounding was better in the treatment group, indicating that the idea of integrating collaboration mechanics into interactive technology designs with the intent to improve grounding has merit. The specific findings for each research question follow.

*RQ*$_1$: To what extent do smartphone apps designed using collaboration mechanics support grounding (the process of creating common ground) between primary and secondary users during face-to-face collaborations?

**Findings for RQ$_1$:** *The experimental study results indicated that such apps support grounding and are capable of facilitating complete common ground. The success of grounding with them is task dependent.*

*RQ*$_2$: To what extent do smartphone apps designed to support grounding impact secondary users’ satisfaction during face-to-face collaborations?

**Findings for RQ$_2$:** *The experimental study results indicated that such apps have the potential to positively impact secondary user satisfaction, performance, and perspective about the primary user’s commitment to the collaboration.*
Discussion

Explanation of Outcomes

*Initial outcomes.* Grounding occurred in both groups regarding the medical history task. However, the time analysis shows that the minimum time on task for the control group was 0 seconds while the treatment group’s minimum time was 54 seconds. Furthermore, none of the providers in the control group conducted patient education related to the medical history task, which was contrasted with a mean time in the treatment group of 23 seconds. Thus, even though grounding for this task occurred in both groups, it occurred throughout the treatment group with the additional benefit of including patient education. This aspect of the time analysis indicates that the encounters in the treatment group were more effective than those in the control group, because all treatment group members accomplished the required task and made time for education, while those in the control group did not.

*Control group outcomes.* In the control group, grounding did not occur for problem identification or medication reconciliation. Participants were not able to confidently identify any aspect of the rash other than it had occurred and had healed. Even though some participants were able to exclude some environmental causes during their discussions with the trained patient actor (e.g., no recent changes to medications), the grounding that did occur involved future patient action if the rash recurred (i.e., contact the office immediately). One participant described the difficulty of evaluating the no longer visible rash thusly:

The rash, that was difficult because once he described the rash, I thought of probably three things it could have been. So, maybe that was probably
about an eight [out of 10] difficulty just because it's not there anymore. So,

I can't treat something or even tell him what it is without having seen it. I
can't treat something I can't see. Participant 3-C (APRN)

Less grounding occurred in this instance, because the rash was gone, and the trained
patient actor’s verbal description was of limited utility.

Regarding medication reconciliation, there was no indication that the providers
were able to glean enough information to be confident that they had correctly identified
the patient’s medication regime. On one hand, medication reconciliation was the most
challenging task for participants in the scenario. The lack of patient medication
knowledge inhibited decision-making about the patient’s healthcare. One participant
commented that:

He didn't know his medication doses and timing, so I was worried that
there was a high risk for error in assuming [that] what he was telling me
was right. It was difficult to make recommendations or a plan without
knowing what those medications were. Participant 3-C (APRN)

On the other hand, the preliminary work for the study indicated that providers typically
have a substantial amount of experience with patients who lack detailed knowledge about
their own medications. This is consistent with what was observed during the study.

Because participants were accustomed to dealing with a lack of medication
information, they knew what questions to ask to devise workarounds. Consequently, they
were able to create a plan of action with the trained patient actor that would result in
getting the correct information. However, even with workarounds, significant treatment
delays could be expected as one participant acknowledged:
What I didn't know was his medications, and I didn't want to guess. I needed that information, but I just have to find it from another source or ask him next time to bring his medications. Participant 2-C (APRN)

The participants indicated that this situation—patient lack of knowledge about their medication details—was typical of encounters with new patients.

It was apparent that grounding did not occur in the control group for the medication reconciliation task. Even though there were successful joint actions between the participants and trained patient actor that culminated in planning activities to get the correct information, these did not enhance the quality of the encounter. In fact, the lack of common ground made the encounters distinctly inefficient in the control group.

*Treatment group outcomes.* In the treatment group, grounding occurred for the problem identification and medication reconciliation tasks. Even though participants could not determine the cause of the rash or swab it for testing, the picture sparked deeper engagement with the trained patient actor about the ailment and allowed participants to exclude some diagnoses. It also seemed to improve general confidence among participants about their interactions with the trained patient actor. The availability of an image of the rash was helpful, as highlighted by this participant:

I like that he took pictures of his wound. It would have been, like I told him, helpful in the future to actually be seen when the situation is acute versus resolved but taking that photo when it was an active rash was helpful—at least would be helpful—to the physician. Participant 6-T (RN)

Even though grounding was not complete for this task, treatment group participants were typically more willing to share detailed information about this type of wound with the
patient. This is noteworthy because rashes are often a difficult clinical issue, so any improvement to communication about such a problem is important. The ability to view an image of the rash clearly aided the communication.

Use of the prototype resulted in common ground being obtained during the medication reconciliation task. Treatment group participants were confident at the end of the interaction that critical and accurate information about the medications had been relayed to them. This allowed them to probe deeper with specific questions or spend more time on patient education.

Treatment group members trusted the information provided from the prototype. For example, Participant 5-T (APRN) remarked that “my gut reaction is that it's accurate and it's a tool that can be shared between the patient and the provider.” The information obtained during the medication reconciliation task was of good enough quality to support medical decision-making. In another example, Participant 6-T (RN) felt that the hospital could dispense medications to a patient admitted for an overnight stay with the level of detail provided by the role-player.

Successful joint actions between the role-player and participants, leading to common ground, occurred during all tasks for the treatment group. However, the completeness of common ground and relevance of the prototype did vary by task. The prototype supported successful joint action and partial common ground for the problem identification task and complete common ground for the medication reconciliation task. The prototype was unnecessary for accomplishing common ground during the medical history task.
Overall in the treatment group, joint actions were comprehensive enough that participants could make plans for treatment based upon the details obtained during the interview. For example, at the end of the encounter, the participants had enough accurate information about medications to maintain the current prescriptions (because they were the correct medicine at the proper dosage for the scenario). This was not the case in the control group. The lack of certainty about medications meant that participants could not evaluate if they were working for the ailments depicted in the scenario.

Even though the post-test questionnaire implies less satisfaction among members of the treatment group, the richness and depth of the findings of the qualitative analysis indicate the opposite and provide a more comprehensive view of the data. The overall qualitative analysis clearly indicated that providers in the treatment group were more satisfied than their peers in the control group. The completeness of information and its contribution to a more successful encounter becomes obvious (because of the qualitative analysis) as reflected in the comments of one participant:

That information that you have to have to make decisions, we didn't have to spend a lot of time figuring that out [because of the prototype]. We were able to quickly get all of that and then move onto here's what we're going to do about the problems that you have, the issues that you have, and go from there. So, we had more time for that, rather than just trying to figure out the historical data. Participant 2-T (Doctor)

For the treatment group, the analysis of satisfaction expressed by the providers combined with the descriptive statistics for the performance of the tasks, indicate that treatment group encounters were more efficient and effective than those in the control group.
The qualitative analysis was a rich source of data and provided detailed insight for answering the research questions. And the quantitative analysis of the task performance supported the conclusions of the qualitative analysis. According to these measures, the use of the smartphone optimized common ground for members of the treatment group. In contrast, the results from the post-test questionnaire were a bit perplexing. For example, research about the impact of introducing examination room computers to the patient-provider encounter showed a higher degree of satisfaction among patients after the introduction of computers [36]. One would expect a similar outcome for clinicians in this research. It is unclear why the perspectives of the participants in each group, as assessed using the post-test questionnaire, were reversed.

Even though the post-test questionnaire implied that the control group’s perceptions were more favorable than the treatment group, this analysis was clearly not accurate based upon the strong positive responses of the treatment group members during the simulations and semi-structured interviews. Furthermore, poor clustering around the mean for satisfaction, common ground, and performance for the control group on the post-test questionnaire, indicated less consensus among them about the variables than in the treatment group.

There are other factors, such as the distinction between the UX and usability, that may help explain how and why the differences in perception occurred. The UX is a person’s emotional response to an interactive system, while usability is a technical aspect that emphasizes how well a person can use a system. (This is why it is said that one designs for a UX, because an emotional response to a technology cannot, in and of itself, be designed.) The placement of a patient-managed technology between the clinician and
patient may have subtly and negatively transformed provider perceptions in the treatment group.

Even though providers in the treatment group liked the usability of the system and found it helpful, they might have perceived it as creating a barrier between themselves and the patients in some way. This idea of a barrier makes sense when considering the emotional nature of the UX and the technical nature of usability. Moreover, the control group was largely made up of primary care professionals who look at patients holistically and longitudinally. The treatment group was largely made up of specialists who may emphasize a procedural perspective because they look at patients for specific ailments and patient relationships tend to be much shorter than the relationships cultivated by their primary care peers. This distinction is a minor point because the descriptive statistics and post-test interviews clearly indicate that the performance was better and the UX was more satisfactory for the treatment group.

Unanticipated outcomes. Finally, a few unanticipated outcomes of insight were gleaned. The first was the possible impact of the technology upon the perspectives of the provider. For example, the semi-structured interviews revealed that the providers in the treatment group were happy with the outcome of the encounter and felt that the information exchange was better than usual. However, they did not record a level of satisfaction higher than their peers in the control group on the post-test questionnaire. The disparity indicates the need for a closer look at the potential impact of patient-centered technology. Another insight was the willingness of providers to become responsible for clinical data from non-clinical sources. An early assumption during the requirements gathering process for designing the prototype was that providers might not be willing to
help manage this type of data. Nothing in the following stages of preliminary work or the
experimental study suggested any reluctance on the part of providers to interact with this
type of data. Rather, the providers considered the data trustworthy or, at least, as
trustworthy as other types of patient provided information that they hold in high regard.

Implications of Results

The medication reconciliation task produced the strongest example of grounding in the
research, which should not be surprising as study participants indicated that 50% to 90% of
their patients did not have accurate medication information with them during a real-
world encounter. This lack of accurate information suggests a gap in knowledge and in
patient-centered tools to aid patient recall. As the experimental study demonstrated, a tool
that provides relevant medication information to providers can facilitate common ground.
The prototype’s interface provided external representations of medications (i.e., images
of each medication) that were clear objects of interest to secondary users. The
representations allowed participants in the treatment group to quickly collaborate with the
role-player about his medications, regardless of the secondary user’s interaction style
with the prototype.

Limitations

The scope of the research was restricted to the relation between usability and common
ground within an mHealth setting. The research initially relied on a thematic analysis
according to common ground theory. The research culminated in a small sample
experimental study using a simulation. Consequently, there are limitations for
generalizability. Form factor and device functionality were relevant to the experimental
study regarding the simulated patient-provider interactions. Additionally, the sample size
was too small for hypothesis testing. Therefore, the results may not be generalizable to collaborations outside the scope of short-duration, face-to-face clinical encounters. Nonetheless, even with a small sample size, the groundbreaking nature of the study offers value to the healthcare community, because it emphasizes the patient as a knowledgeable collaborator—and as one who (through mHealth) can share their personal health information in a manner that improves the overall efficiency and effectiveness of provider care.

Future Research and Recommendations

This study is the first to explore common ground using both primary and secondary UXs. The results indicate that there is a need to consider primary and secondary users when designing a single system for information sharing between those with expert and non-expert levels of knowledge. To improve generalizability, the study should be replicated with a larger sample and providers who work in the same hospital or practice. It would be best to limit the study participants to one skill or specialty.

Limiting participants has several advantages for ecological validity. For example, EMRs and intake sheets with simulated patient data can be created using the systems common to the organization. This will increase realism in the simulation for participants. Furthermore, with the standardized procedures, training, and tools common to a single organization and specialty, confounding variables can be limited.

Finally, the prototype used for the simulation should be a smartphone app running on the device rather than a responsive design website. There was some latency accessing the website based upon location and network quality, which caused small delays. A native app running on a smartphone mitigates the impact of a slow running website and will
more accurately capture shorter encounter times due to the faster load times for a native app.

**Summary**

During the preliminary work, the priorities that emerged for providers in the type of encounter simulated were to conduct medication reconciliation, problem identification, and then health history. The priorities, regarding the technology and its efficacy as a tool to facilitate communication, were supported during the experimental study. For example, peak usefulness of the prototype was demonstrated whenever participants attempted to glean highly clinical data (i.e., detailed medication information) from the primary user, who is typically a non-clinical source for such information. Additionally, participants in the treatment group had improved confidence because the rash image was available. Finally, while technology did not improve or detract from grounding for members of the treatment group during the medical history task when compared to the control group, it seemed to create efficiencies for the overall encounter that allowed all members of the treatment group to complete the task (while all members of the control group did not).

The alignment of the perceptions of the relative importance of the respective tasks from providers to the actual creation of common ground during the experimental study, should be interpreted as providing a level of awareness for design decisions regarding the allocation of time and other resources. If tasks are difficult to accomplish (i.e., medication reconciliation), then attempts to promote grounding using technology may be a good use of resources, while it may be a poor use of resources for easy tasks (i.e., medical history). This identification of importance and the relation to common ground is a vital insight for the overall body of secondary user research.
Regarding outcomes in the different experimental groups, it is not that grounding did not occur in the control group—it did. Rather, it is the relevance of the common ground achieved for solving the problem at the center of the need for communication that is at issue. Participants noted that the attainment of common ground during a first encounter with a new patient was frequently rare in real life. They also indicated that they would support patients’ uses of smartphones as a tool by which to improve face-to-face communications during encounters. This participant highlights why smartphone use would be acceptable:

The easiest thing about sharing information with this patient was his ability to use technology to show me, so that we were both on the same page. As opposed to [a verbal] description, [where] I paint my own. Then, we're both on apples to apples, instead of me trying to paint in my head what he's describing. Participant 4-T (RN)

This study indicated that well-designed systems that deepen the engagement of patients in their own healthcare, while improving near-term communication with providers has a place in HIT.

The provider responses in the treatment group reinforced design decisions about the information that should be made available to secondary users. Overall, the utility of patient-controlled devices during a first encounter with a patient depends as much upon the difficulty for the provider of normally obtaining the information intended to be shared, and its impact upon immediate decision-making, as on the HCI design decisions. Medication reconciliation is a difficult task that is necessary for successful treatment decisions. In real life, inconclusive reconciliation is so routine that it is expected among
providers. The introduction of technology to mitigate a patient’s personal lack of knowledge has the potential to create useful common ground within the dyad for this type of complex healthcare task. This observation is another critical insight for the overall body of secondary user research.
Conclusion

The experimental study is one of the first studies to directly demonstrate that not all secondary UXs are meaningful for design. For example, grounding occurred during the medical history task in the control and treatment groups. Any marginal improvement due to implementation of technology, where grounding occurs regardless of technology, is probably not worth the effort. The fact that common ground was only completed in the treatment group and during medication reconciliation (an essential enabler for healthcare decision-making) indicates that an investment in the secondary UX for high payoff tasks is valuable.

Combining the notions of common ground, HCI design, and smartphone technology resulted in a prototype that improved the efficiency and effectiveness of face-to-face collaboration for secondary users with the primary user. The prototype clearly facilitated a higher quality of information exchange than normal. Thus, the investigation substantiated the notion that properly designed interactive systems have the potential to facilitate common ground while providing a satisfactory secondary UX.
